Statistical Physics (Gibbs, 1902). In large systems of particles, each particle occupies a site and can be in different states. The total energy of the system is composed of an external potential and a potential due to *interactions* of groups of particles. It is assumed that particles that are close to each other (i.e., they are “neighbors”) interact while those that are not close to each other do not interact.

Genetics & Path Analysis. (Wright, 1921, 1923, 1934). In studying the heritability of properties of natural species, graphs were used to represent *directed relations*. Arrows point from a “parent” to a “child”. These ideas were taken up by Wold (1954) and Blalock (1971) in economics and social sciences and lead to what we know as path analysis.

Interactions in 3-way contingency tables. Barlett (1935). The notion of interaction in contingency tables studied by Barlett is formally identical to the notions used in statistical physics. The development of graphical models for multi-way contingency data

stems from a paper by Darroch, J.N., Lauritzen, S.L., & Speed, T.P. (1980).

Usefulness of Graphical Models

Independence

Sparse Data

Modeling Incomplete Table

Graphical models are useful and are widely applicable because

1. Graphs visually represent scientific content of models and thus facilitate communication.
2. Graphs break down complex problems/models into smaller and simpler pieces that can be studied separately.
3. Graphs are natural data structures for digital computers.

We'll be using graphs to

1. Help determine when marginal and partial associations are the same such that we can *collapse* a multi-way table into a smaller table (or tables) to study certain associations.
2. Represent substantive theories and hypotheses, which correspond to certain loglinear/logit models.

Some terminology & definitions (common to all graphical models)...

Independence

Sparse Data

Modeling Incomplete Table

Vertices (or “nodes”) are points that represent variables.

Edges are lines that connect two vertices.

The presence of an edge between two vertices indicates that an association exists between the two variables.

The absence of an edge between two vertices indicates that the two variables are independent.

We will be restricting our attention to **undirected** relationships, so our lines won't have arrows on them (lines with arrows represent directed relationships).

A **Graph** consists of a set of vertices and edges.

Sparse Data

Modeling Incomplete Table

Path is a sequence of edges that go from one variable to another.

Separated. Two variables are said to be separated if all paths between the two variables intersect a third variable (or set of variables).

Even More Definitions

A **Clique** is a set of vertices (variables) where each variable is connected to every other variable in the set.

This is also known as a “complete graph” and if this is part of a larger graph, a “complete subgraph”.

Fundamental Result (cornerstone of graphical modeling):

Two variables are conditionally independent given any subset of variables that separates them.

Modeling Incomplete Table

Collapsibility in 3–Way Tables

Under certain conditions, marginal associations and partial associations are the same (i.e., the partial odds ratios equal the marginal odds ratios).

The collapsibility condition for 3–way tables is

For 3–way tables, X - Y marginal and partial odds ratios are identical if either

- Z and X are conditionally independent, or
- Z and Y are conditionally independent.

In other words,

The X - Y marginal and partial odds ratios are identical if either the

- Log-linear model (XY, ZY) holds, or
- Log-linear model (XY, XZ) holds.

Model Building for Logit and Log-linear Models

Modeling Ordinal Relationships

Collapsibility & Logit Models

The collapsibility condition for log-linear models applies to logit models as well.

Example: Problem 5.14 (page 138). Data from NCAA study of graduation rates of college athletes:

Race	Sex	Graduates	Sample Size
White	women	498	796
White	men	878	1625
Black	women	54	143
Black	men	197	660

The best logit model for these data is

$$\text{logit}(\pi_{ij}) = \alpha + \beta_i^R + \beta_j^S$$

Recall that $\exp(\beta_f^S - \beta_m^S)$ equals the odds ratio for graduation and gender of the athlete holding race fixed; that is,

$$\theta_{SG(i)} = \exp(\beta_f^S - \beta_m^S)$$

Model Building for Logit and Log-linear Models

Modeling Ordinal Relationships

Slide 16 of 116

Collapsibility & Logit Models (continued)

The logit model $\text{logit}(\pi_{ij}) = \alpha + \beta_i^R + \beta_j^S$ corresponds to the no 3-factor association log-linear models; that is, (RS, RG, SG) where G = whether the student athlete graduated or not.

If the logit model

$$\text{logit}(\pi_{ij}) = \alpha + \beta_j^S$$

had fit, which corresponds to the (RS, SG) log-linear model, then we could have studied the gender-graduation relationship by looking at the gender \times graduation marginal table.

According to the collapsibility condition, if the (RS, SG) log-linear model fit, then the partial S-G odds ratio equals the marginal odds ratio; that is,

$$\theta_{SG(i)} = \theta_{SG}$$

Slide 17 of 116

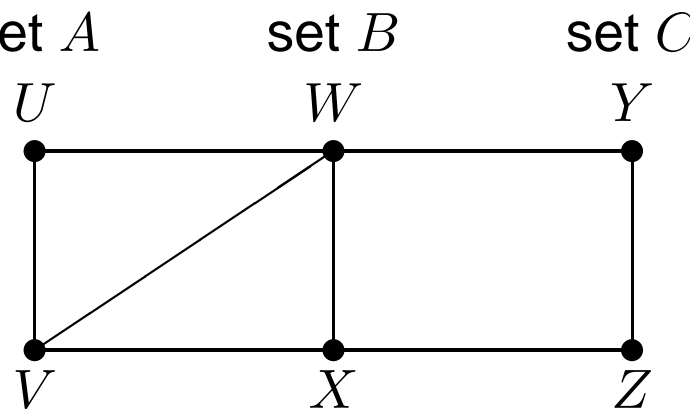

Collapsibility for Multiway Tables

from Agresti

Suppose that variables in a model for a multiway table partition into three exclusive subsets, A , B , and C , such that B separates A and C ; thus, the model does not contain parameters linking variables from A with variables from C . When one collapses the table over the variables in C , model parameters relating variables in A and model parameters relating variables in A with variables in B are unchanged.

Graphically, each path between variables in set A and variables in set C involve at least 1 variable in set B .

Modeling Ordinal Relationships

Using Graphs to Guide Modeling

Example: Data from a concurrent-task detection experiment. (Olzak, 1981; Olzak & Wickens, 1983; Wickens, 1989; Anderson, 2002; Kroonenberg & Anderson, 2006).

There are two signals (i.e., vertically oriented sin ways):

- H — A high frequency one.
- L — A low frequency one.

On each trial for each potential signal, subjects rated on a 1 to 6 scale whether a signal was present or not where 1 indicates they were sure that no signal was presented and 6 indicates that they were sure that a signal was presented. Each subject performed 2,000 trials where there were 500 consisting of 2×2 combinations of H and L signals being present or absent.

So there are 2 response variables:

X for the rating of the H signal
 Y for the rating of the L signal.

... and there were 2 factors (conditions) were L and H present and/or absent

Modeling Ordinal Relationships

High Frequency Signal

Low Freq	Y	High Frequency Signal											
		Absent						Present					
		X = 1	2	3	4	5	6	1	2	3	4	5	6
Absent	1	69	6	1	1	0	0	10	5	2	11	16	28
	2	34	20	10	3	1	0	8	5	11	43	27	38
	3	43	24	13	9	1	0	9	6	7	28	32	45
	4	78	40	20	6	0	1	8	6	14	19	23	22
	5	32	38	17	5	4	0	4	5	7	6	18	18
	6	5	14	3	2	0	0	0	1	2	3	5	8
Present	1	4	1	0	0	0	0	5	0	1	4	4	9
	2	5	3	2	1	0	0	0	1	3	6	9	27
	3	8	6	3	1	0	0	2	3	2	11	27	20
	4	36	25	18	3	1	0	9	12	11	10	23	31
	5	83	69	26	6	1	0	16	7	5	19	23	40
	6	127	50	12	7	2	0	21	14	13	20	21	61

With four variables, there are many possible models to fit.
 However, we don't need to consider all models that could be fit to the data.

Model Building for Logit and Log-linear Models

Modeling Ordinal Relationships

Since H and L were fixed by the experimenter (i.e., “fixed by design”), all models should include terms λ^{HL} for the HL association. The simplest model would be that a subject responds randomly

The log-linear model: (HL, X, Y) .

$$G^2 = 2265.57, df = 130, p < .01$$

Detectable Signals

The subject can detect the signals & detecting one does not influence detection of the other (i.e., subject does what the experimenter asked).

Log-linear model:

$$(HL, XH, YL)$$

This is a “base” model to which we can add more complicated forms of associations.

$$G^2 = 2, 152.26, df = 120, p < .01$$

If one signal or the other was not detectable, then we **might** have another base model (e.g., (HL, XH, Y) or (HL, LY, X)).

Modeling Ordinal Relationships

Association to the unrelated signal

In this model, responses to one signal are influenced by whether both signals are present and/or absent (i.e., the appropriate and inappropriate signal).

The log-linear model

$$(HLX, HLY)$$

$$G^2 = 221.43, df = 100, p < .01$$

- X and Y are conditionally independent given H and L .
- A more restricted alternative model that also has this graphical representation, (HL, HX, HY, LX, LY) .
- Since we're only considering models that "make sense" (i.e. that are interpretable), we wouldn't include a model such as

All pairwise associations.

The log-linear model (HL, HX, HY, LX, LY, XY) .

$$G^2 = 113.82, df = 85, p = .02$$

It's graphical representation is

This is also the representation of many other log-linear models with dependencies, including model with 4-way interaction (i.e. saturated model).

This is the most complex graph, but there are interesting log-linear models that have this representation.

Modeling Ordinal Relationships

Another Model

We can add three-factor terms to the all pairwise association model. Some of these all have reasonable interpretations.

For example, consider the model that adds λ^{HLY} (i.e., (HLY, HY, LY, XY)). The λ^{HLY} terms imply that delectability of the L signal (measured by Y) is affected by the presence of the H signal.

It's graphical representation is

Fit of this model

$$G^2 = 98.06, \quad df = 80, \quad p = .08$$

Model Building for Logit and Log-linear Models

Modeling Ordinal Relationships

Eg: 4-way Table with Time Ordering

Using a suggested ordering of the variables in terms of time and causal hypotheses and show how to “decompose” a model into smaller pieces.

Example from Agresti, 1990; The variables:

G for gender.

PMS for premarital sex.

EMS for extra martial sex.

M for marital status (divorced, still married).

We'll depart somewhat from the graphical models that we've discussed so far and talk about [directed relationships](#).

The point in time at which values of variables were determined:

G PMS EMS M

Any variable to the right of others could be a response & those left of it explanatory.

Modeling Ordinal Relationships

Slide 30 of 116

Breaking down the analysis

We could analyze these data in three stages:

Stage	Response	Explanatory
(1)	PMS	Gender
(2)	EMS	Gender, PMS
(3)	M	Gender, PMS, EMS

To further guide the modeling consider the following figure, which might have been hypothesized as the existing causal structure for the variables.

Stage 1: PMS is the response & G explanatory.

$$G^2 [(G, P)] = 75.26, df = 1, \text{ and } p < .0001.$$

Sample (marginal) odds ratio $\hat{\theta}_{GP} = .27$ (or $1/.27 = 3.70$).

● Next Stage

● Last Stage

Model Building for Logit and Log-linear Models

Modeling Ordinal Relationships

Next Stage

Stage 2: EMS is the response and G & PMS are possible explanatory variables.

Model	df	G^2	p	X^2	p
(GP, E)	3	48.92	< .001	56.77	< .001
(GP, PE)	2	2.91	.23	2.95	.23
(GP, GE, PE)	1	.00 ^a	.98	.00 ^a	.98

a. Value = .0008.

Loglinear model (GP, PE) fits pretty well.

The estimated P - E odds ratio $\hat{\theta}_{EP} = 3.99$.

The marginal odds ratio is also equal to 3.99, and the reason why can be seen by looking at the figure for the model that fit:

Model Building for Logit and Log-linear Models

Modeling Ordinal Relationships

Last Stage

Stage 3: M is the response, while G, PMS and EMS are all explanatory variables.

Model	<i>df</i>	G^2	<i>p</i>
(EGP, EM, PM)	5	18.16	< .01
(EGP, EMP)	4	5.25	.26
(EGP, EMP, GM)	3	.70	.98

Notes:

- (EGP, EM, PM) corresponds to the original figure.
- (EGP, EMP) adds an interaction between EMS and PMS with respect to M, marital status (from previous analyses we knew that there was a strong & important $EMS \times PMS \times M$ effect).
- (EGP, EMP, GM) adds a main effect for Gender with respect to predicting M.
- (EGP, EMP) and (EGP, EMP, GM) are more complex than implied by original figure.

Modeling Ordinal Relationships in 2–Way Tables

- Loglinear models for contingency tables treat all variables as nominal variables.
- If there is an ordering of the categories of the variables, this is not taken into account
- Could rearrange the rows and/or columns of a table and we would get the same fitted odds ratios for the data as we would given the ordinal ordering of the rows and/or columns.

High School and Beyond: Consider **Program type** (Vocational/technical, general and academic) and **SES** (low, middle, high).

SES	Program Type		
	Vo/Tech	General	Academic
Low	45	50	44
Middle	82	70	147
High	20	25	117

Slide 34 of 116

In between independence & saturated models

For the SES \times Program type data, if the two variables are independent, then we have

$$\log(\mu_{ij}) = \lambda + \lambda_i^S + \lambda_j^P$$

This model fails to fit the data, $df = 4$, $G^2 = 53.72$, $p < .001$, which leaves us with the saturated model

$$\log(\mu_{ij}) = \lambda + \lambda_i^S + \lambda_j^P + \lambda_{ij}^{SP}$$

We can use ordering of SES levels and assign scores to them and we'll guess at the ordering of the program types, which we can use our model.

Given scores for the rows $\{u_1 \leq u_2 \dots \leq u_I\}$ and scores for the columns $\{v_1 \leq v_2 \leq \dots \leq v_J\}$, then we can model the dependency between the variables:

$$\log(\mu_{ij}) = \lambda + \lambda_i^S + \lambda_j^P + \beta u_i v_j$$

This model is known as the “**linear by linear association model**”.

Tests of Conditional Independence

Sparse Data

Model Building for Logit and Log-linear Models
Modeling Incomplete Table

Linear by Linear Association Model

$$\log(\mu_{ij}) = \lambda + \lambda_i^S + \lambda_j^P + \beta u_i v_j$$

- It's called the “linear by linear association model,” because...

For each row i , the association is a linear function of the columns,

$$\lambda_{ij}^{SP} = (\beta u_i) v_j$$

For each column j , the association is a linear function of the rows.

$$\lambda_{ij}^{SP} = (\beta v_j) u_i$$

- Only has 1 more parameter than the independence model (i.e., β), so it is “in between” independence and the saturated models.
- If $\beta > 0$, then X and Y are positively associated (i.e., X tends to go up as Y goes up).
- If $\beta < 0$, the X and Y are negatively associated.

Ordinal Tests of Independence

Tests of Conditional Independence

Sparse Data

Model Building for Logit and Log-linear Models
Modeling Incomplete Table

Linear by Linear Association Model (continued)

$$\log(\mu_{ij}) = \lambda + \lambda_i^S + \lambda_j^P + \beta u_i v_j$$

- The odds ratio for any 2×2 sub-table is a direct function of the row and column scores and β .

$$\begin{aligned} \log\left(\frac{\mu_{ij}\mu_{i'j'}}{\mu_{i'j}\mu_{ij'}}\right) &= \log(\mu_{ij}) + \log(\mu_{i'j'}) - \log(\mu_{i'j}) - \log(\mu_{ij'}) \\ &= \beta(u_i v_j + u_{i'} v_{j'} - u_{i'} v_j - u_i v_{j'}) \\ &= \beta(u_i - u_{i'})(v_j - v_{j'}) \end{aligned}$$

The strongest associations occur in the extreme corners of the table, which is where the differences between scores is the largest.

The smallest associations occur for rows and columns that have scores that are more nearly equal.

Ordinal Tests of Independence

Tests of Conditional Independence

Sparse Data

Model Building for Logit and Log-linear Models
Modeling Incomplete Table

Slide 37 of 116

Example of linear by linear model

For the high school data example, it seems reasonable to assign equally spaced scores for the levels of SES:

$$u_1 = 1, \quad u_2 = 2, \quad u_3 = 3$$

For the program types, it seems reasonable to order them as:

Vo/Tech General Academic

Guess that Vo/Tech and General should be closer together than are General and Academic; therefore, let's try

$$v_1 = 1, \quad v_2 = 2 \quad v_3 = 4$$

Using these scores

Model	<i>df</i>	G^2	<i>p</i>	Δdf	ΔG^2	<i>p</i>
Independence	4	53.715	< .001	—	—	—
L by L	3	5.980	.10	1	47.74	< .001

Ordinal Tests of Independence

Tests of Conditional Independence

Sparse Data

Estimated Parameters & Odds Ratios

$$\hat{\beta} = .32 \quad \text{and} \quad \exp(.32) = 1.38,$$

The odds ratio for a unit change in row and column scores equals 1.38 (e.g., odds ratio for low–middle SES and vo/tech–academic subtable).

The extreme corners of our table, which correspond to the low & high SES levels and program types vo/tech & academic:

$$\hat{\theta} = \exp [.3214(3 - 1)(4 - 1)] = \exp(.3214(6)) = 6.88$$

The odds of attending an academic versus a vo/tech program if you're high SES is 6.88 times the odds if you're low SES.

Scale		0	1.00	0.00	1.00	1.00		

NOTE: The scale parameter was held fixed.

Choice of Scores

- Sets of scores with the same spacing between them will lead to the same goodness-of-fit statistics, fitted counts, odds ratios, and $\hat{\beta}$.

For HSB data, the following set of scores for the columns (hsp) would yield that same result: $v_1 = 0$, $v_2 = 1$, $v_3 = 3$.

- Two sets of scores with the same relative spacing will lead to the same goodness-of-fit statistics, fitted counts, and odds ratios, but different estimates of β . e.g.,

$$v_1 = 2, \quad v_2 = 4 \quad v_3 = 8$$

With these column (HSP) scores, $\hat{\beta} = .1607$.

- ◆ Odds ratio for low & middle (or middle & high) and vo/tech & general

$$\hat{\theta} = \exp[.1607(2 - 1)(4 - 2)] = \exp[.1607(2)] = \exp[.3214] = 1.38$$

- ◆ Odds ratio for low & high SES and program types vo/tech & academic:

$$\hat{\theta} = \exp[.1607(3 - 1)(8 - 2)] = \exp[.1607(12)] = 6.88$$

Ordinal Tests of Independence

Tests of Conditional Independence

Sparse Data

Model Building for Logit and Log-linear Models
Modeling Incomplete Table

Uniform Association Model

When scores are consecutive integers (or equally spaced scores) are used, e.g.,

$$u_1 = 1, \quad u_2 = 2, \quad \dots, u_I = I$$

$$v_1 = 1, \quad v_2 = 2, \quad \dots, v_J = J$$

This special case of L by L model is the “[Uniform Association Model](#).”

The uniform association model for the HSB example:

Model	df	G^2	p
Independence	4	53.715	< .01
L by L	3	5.980	.10
Uniform Assoc	3	11.74	< .01

This model is called the Uniform Association Model, because the odds ratios for any two adjacent rows and any two adjacent columns equals

$$\theta = \exp \beta(u_i - u_{(i-1)})(v_j - v_{(j-1)}) = \exp(\beta)$$

The “[Local Odds Ratio](#)” equals $\exp(\beta)$ and is the same for adjacent rows and columns.

Ordinal Tests of Independence

Tests of Conditional Independence

Sparse Data

Model Building for Logit and Log-linear Models
Modeling Incomplete Table

Model/Test	df	G^2	p	Estimates
Independence	12	44.96	< .001	
M^2	1	36.261	< .001	$r = .20$
Uniform Assoc	11	8.67	.65	$\hat{\beta} = .24, ASE = .0412$

$H_o : \beta = 0$ vs $H_a : \beta \neq 0$,

L.R. test: $G^2 = (44.96 - 8.67) = 36.29, df = 1, p < .01$

The estimated local odds ratio equals $e^{.24} = 1.28$.

For the extreme corners of the table, the estimated odds ratio equals $e^{.24(3)(4)} = 18.5$

Unlike the tests of ordinal association that are based on a correlation, these models provide us with estimated odds ratios for the table, as well as permit us to check residuals, etc.

Back to HSB

For the HSB data, using equally spaced scores we find that

$$M^2 = 40.87, \quad df = 1, \quad p < .001, \quad \text{and} \quad r = .26$$

However, when we fit the linear by linear association model with equal scores it did not fit the data (this is shown in the residuals, as well).

Model	<i>df</i>	G^2	<i>p</i>
Independence	4	53.715	< .01
L by L (unequal spacing)	3	5.980	.10
Uniform Assoc (equal spacing)	3	11.74	< .01

Ordinal Tests of Independence

Tests of Conditional Independence

Sparse Data

Model Building for Logit and Log-linear Models
Modeling Incomplete Table

Ordinal Tests of Independence

CMH test was one way to test of ordinal association (or independence), but now we have a model based method. Using the linear by linear association model

$$\log(\mu_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y + \beta u_i v_j$$

The likelihood ratio test and the Wald test of the hypothesis

$$H_o : \beta = 0$$

is the same as testing

$$H_o : \text{independence}$$

Using the likelihood ratio test,

$$G^2(I|L \times L) = G^2(I) - G^2(L \times L)$$

For the HSB data: $G^2(I|L \times L) = 53.715 - 5.98 = 47.73$ with $df = 4 - 3 = 1$, and $p < .001$.

The Wald test: $\left(\frac{\hat{\beta}}{ASE}\right)^2 = \left(\frac{.3199}{.0485}\right)^2 = 43.55$

The CMH test is the efficient score test for this same hypothesis (i.e., $M^2 = 40.87$, $df = 1$, $p < .001$).

L by L	(unequal spacing)	3	5.980	.10
Nominal HSP × Ordinal SES	(equal spaced SES)	2	2.30	.32
<i>RC</i> association	(scores estimated)	1	1.74	.19

- The estimated parameters for the SES × HSP association in the nominal × ordinal model

$$\hat{\beta}_{\text{votech}} = .000, \quad \hat{\beta}_{\text{general}} = -.005 \quad \hat{\beta}_{\text{academic}} = .864$$

- *RC* association model estimates the scores for both SES and HSP, as well as β (the “association parameter”).

HSP	est. score	SES	est. score	and $\hat{\beta} = 1.000$
VoTech	-.423	Low	-.669	
General	-.393	Middle	-.071	
Academic	.816	High	.740

Tests of Conditional Independence

Sparse Data

Modeling Incomplete Table

- This approach is not restricted to models for 2-way tables and log-linear models. You add use scores in log-linear and/or logit model for higher-way tables.
- There are more general models where the scores are estimated from the data. For 2-way tables, this includes Goodman's "row effects" model (R), "column effects" model (C), "row + column" effects model ($R + C$), and the row-column model RC). There are generalizations of these models to multiple dimensions and higher-way tables.
- There are also models for ordinal *response* variables that take into account the ordering of the categories.
- Other ordinal models (Vermunt, J.K. (2001). *Sociological Methodology*).
- Linear by linear with latent variable interpretations (Anderson & Vermunt, 2000; Anderson, 2002; Anderson & Yu, 2007; Anderson, Li & Vermunt, 2007; Anderson, Verkuilen & Peyton, in press; etc.).

Tests of Conditional Independence

Sparse Data

Modeling Incomplete Table

A good model for Wickens & Olzak data is

(HLY, HY, LY, XY) ,

$$\log(\mu_{ijkl}) = \lambda + \lambda_i^H + \lambda_j^L + \lambda_{ij}^{HL} + \lambda_k^X + \lambda^Y + \lambda_{kl}^{XY} + \lambda_{ik}^{HX} + \lambda_{jl}^{LY} + \lambda_{ijl}^{HLY}$$

Let $u_k = 1, \dots, 6$ and $v_l = 1, \dots, 6$ be scores for the high and low responses, respectively. We can use these instead of nominal responses:

$$\log(\mu_{ijkl}) = \lambda + \lambda_i^H + \lambda_j^L + \lambda_{ij}^{HL} + \lambda_k^X + \lambda^Y + \lambda_{kl}^{XY} + \lambda_i^H u_k + \lambda_j^L v_l + \lambda_{ij}^{HL} v_l$$

This model doesn't fit particularly well ($G^2 = 259.1267$, $df = 100$, $p < .01$), but one with estimated scores does.

Eg. of a Latent Variable Model

$$\log(\mu_{ijkl}) = \lambda + \lambda_{ij}^{HL} + \lambda_k^X + \lambda^Y + \lambda_{kl}^{XY} + \sigma_1^2 \nu_{1(ij)}^{HL} \nu_k + \sigma_2^2 \nu_{2(ij)}^{HL} \nu_l$$

$$G^2 = 138.35, df = 98, p = .01, D = .082.$$

But there were 2 subjects and this graph describes both. For the other subject ("subject A"), $G^2 = 111.12, df = 97, p = .15, D = .086$.

Tests of Conditional Independence

Sparse Data

Modeling Incomplete Table

Tests of Conditional Independence

General terms of testing whether row (X) and column (Y) classifications are independent conditioning on levels of a third variable (Z).

There are 3 kinds of tests:

1. Likelihood ratio tests (“LR” for short).
 - (a) Comparing conditional independence model to homogeneous association model.
 - (b) Comparing conditional independence model to saturated model.
2. Wald tests.
3. Efficient score tests, i.e. Generalized CMH.

The LR and Wald tests require the estimation of (model) parameters, while the Efficient score tests do not.

Model Based Tests of Conditional Independence

The likelihood ratio test. We compare the fit of the conditional independence model and comparing it to the homogeneous association model.

For example to test whether X and Y are conditionally independent given Z , i.e.,

$$H_0 : \quad \text{all} \quad \lambda_{ij}^{XY} = 0$$

The likelihood ratio test statistic is

$$G^2 [(XZ, YZ)|(XY, XZ, YZ)] = G^2(XZ, YZ) - G^2(XY, XZ, YZ)$$

with $df = df(XZ, YZ) - df(XY, XZ, YZ)$.

● So far
Model Building for Logit and Log-linear Models

● Nominal-Ordinal Case

Notes Regarding Likelihood Ratio Test

- This test assumes that (XY, XZ, YZ) holds.
- This single test is preferable to conducting $(I - 1)(J - 1)$ Wald tests, one for each of the non-redundant λ_{ij}^{XY} 's. For our example, the result is pretty unambiguous; that is,

Parameter	Estimate	ASE	Wald	p
λ_{lv}^{SP}	1.8133	.3233	31.450	< .0001
λ_{lg}^{SP}	1.6600	.3033	29.952	< .0001
λ_{mv}^{SP}	1.1848	.2786	18.079	< .0001
λ_{mg}^{SP}	.8004	.2639	9.198	.0024

- For binary Y , this is the same as performing the likelihood ratio test of whether $H_0 : \text{all } \beta_i^X = 0$ in the logit model

$$\text{logit}(\pi_{ik}) = \alpha + \beta_i^X + \beta_k^Z$$

which corresponds to the (XY, XZ, YZ) log-linear model.

● Nominal–Ordinal Case

For $2 \times 2 \times K$ tables, this likelihood ratio test of conditional independence has the same purpose as the Cochran–Mantel–Haenszel (CMH) test. For the CMH test,

- It works the best when the partial odds ratios are similar in each of the partial tables.
- It's natural alternative (implicit) hypothesis is that of homogeneous association.
- CMH is the efficient score tests of $H_0 : \lambda_{ij}^{XY} = 0$ in the log-linear model.

Direct Goodness-of-Fit Test

We compare the fit of the conditional independence model to the saturated model; that is,

$$G^2 [(XZ, YZ)|(XYZ)] = G^2(XZ, YZ) - G^2(XYZ)$$

The null hypothesis for this test statistic is

$$H_0 : \text{all } \lambda_{ij}^{XY} = 0 \quad \text{and} \quad \text{all } \lambda_{ijk}^{XYZ} = 0$$

Example: **G**= Gender , **S**= SES, and **P**= Program type. Testing whether SES and program type are independent given gender,

$$H_0 : \text{all } \lambda_{ij}^{SP} = 0 \quad \text{and} \quad \text{all } \lambda_{ijk}^{GSP} = 0$$

● Example Continued...

● Estimated Partial Odds Ratios

● So far
Model Building for Logit and Log-linear Models

● Nominal–Ordinal Case

A direct goodness-of-fit test does not assume that (XY, XZ, YZ) holds, while using $G^2 [(XZ, YZ)|(XY, XZ, YZ)]$ does assume that the model of homogeneous association holds.

Disadvantages of the goodness-of-fit test as a test of conditional independence

1. It has lower power.
2. It has more df than the Wald test, the CMH, and the LR test (i.e., $G^2 [(XZ, YZ)|(XY, XZ, YZ)]$).

Ordinal Conditional Association

If the categories of one or both variables are ordered, then there are more powerful ways of testing for conditional independence.

With respect to models, we can use a generalized linear by linear model, more specifically a “homogeneous linear by linear association” model.

$$\log(\mu_{ijk}) = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \beta u_i v_j + \lambda_{ik}^{XZ} + \lambda_{jk}^{YZ}$$

where u_i are scores for the levels of variable X , and v_j are scores for the levels of variable Y .

Notes:

- The model of conditional independence is a special case of this model; that is, $\beta = 0$
- This model is a special case of the homogeneous association model.

Model Building for Logit and Log-linear Models

● Nominal-Ordinal Case

Example Continued...

- The null hypothesis for the likelihood ratio test statistic (in the last row of top table) is $H_O : \beta = 0$ with $df = 1$; whereas, in the lower table, it is

$$H_O : \text{all } \lambda_{ij}^{SP} = 0 \text{ with } df = 4$$

- Comparing G^2/df for the two tests,

$$53.548/4 = 13.387 \quad \text{versus} \quad 48.043/1 = 48.043$$

- **Conclusion:** If data exhibit linear by linear partial association, then using scores gives you a stronger (more powerful) test of conditional independence.
- The Wald statistic for β equals 43.939, $df = 1$, and $p < .0001$. This is comparable to the new likelihood ratio test statistic.

● Nominal–Ordinal Case

Estimated Partial Odds Ratios

$\hat{\beta} = .3234$. The estimated partial odds ratio equals

$$\hat{\theta}_{SP(k)} = \exp [.3234(u_i - u_{i'})(v_j - v_{j'})]$$

For example, the smallest partial odds ratio is for low and middle SES and votech and general programs,

$$\hat{\theta}_{SP(k)} = \exp [.3234(2 - 1)(2 - 1)] = \exp(.3234) = 1.38$$

The largest partial odds ratio is for low and high SES and votech and academic programs equals

$$\hat{\theta}_{SP(k)} = \exp [.3234(3 - 1)(4 - 1)] = \exp(1.9404) = 6.96$$

Variable		Type of Test		
		Likelihood Ratio	Wald	(Generalized) CMH
Row	Column			
Nominal	Nominal	X	X	
Nominal	Ordinal			
Ordinal	Ordinal	X	X	

Next, the model based nominal-ordinal case.

For the nominal-ordinal case, we only put in scores for the categories of the ordinal variable and estimate a β for each category of the nominal variable.

Nominal–Ordinal Case

For example, if only have put in scores for SES, we fitting the model

$$\log(\mu_{ijk}) = \lambda + \lambda_i^S + \lambda_j^P + \lambda_k^G + \beta_j^P u_i + \lambda_{ik}^{SG} + \lambda_{jk}^{PG}$$

where u_i are scores for SES (i.e., $u_1 = 1$, $u_2 = 2$, and $u_3 = 3$), and β_j^P are estimated parameters.

Model	Goodness-of-fit Test			Likelihood Ratio Test		
	df	G^2	p	Δdf	ΔG^2	p
(GS, GP, SP)	4	1.970	.74	—	—	—
(GS, GP)	8	55.519	< .0001	4	53.548	< .001
$(GS, GP, SP) - L \times L$	7	7.476	.38	3	5.505	.14

(GS, GP)	8	55.519	< .0001	2	51.443	< .001

For the nominal–ordinal model, $\hat{\beta}_{votech}^P = -.8784$ & $\hat{\beta}_{gen}^P = -.8614$,
 \implies the “best” scores for VoTech and General programs are much
 closer together than we had been assuming.

Nominal	Ordinal	X	X	
Ordinal	Ordinal	X	X	

To complete our table, we need to talk about efficient score tests for testing conditional independence for each of the three cases.

The efficient score test of conditional independence of X and Y given Z for an $I \times J \times K$ cross-classification is a generalization of the Cochran-Mantel-Haenszel statistic, which we discussed as a way to test conditional independence in $2 \times 2 \times K$ tables.

For each of three cases, the test statistic is a **Generalized CMH Statistic**.

- So far
- Model Building for Logit and Log-linear Models
- Nominal-Ordinal Case

- The generalized CMH statistic is appropriate when the partial associations between X and Y are comparable for each level of Z (the same is true for the LR test $G^2 [(XZ, YZ)|(XY, XZ, YZ)]$).
- **Ordinal-Ordinal.** The generalized CMH uses a generalized correlation and tests for a linear trend in the X - Y partial association.
 - ◆ The null hypothesis is $H_O : \rho_{XY(k)} = 0$, and the alternative is $H_A : \rho_{XY(k)} \neq 0$.
 - ◆ The statistic gets large
 - as the correlation increases.
 - as the sample size per (partial) table increases.
 - ◆ When H_O is true, the test statistic has an approximate chi-square distribution with $df = 1$.

● Example Continued...

● Estimated Partial Odds Ratios

● So far
Model Building for Logit and Log-linear Models

● Nominal-Ordinal Case

- The CMH for ordinal \times ordinal is the efficient score test for testing $H_0 : \beta = 0$ in the homogeneous linear by linear association model:

$$\log(\mu_{ijk}) = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \beta u_i v_j + \lambda_{ik}^{XZ} + \lambda_{jk}^{YZ}$$

where u_i are scores for the levels of variable X and v_j are scores for the levels of variable Y .

- HSB Example: Generalized CMH statistic = 46.546, $p < .0001$.
On the handout, it is labeled “Nonzero Correlation”, which is the alternative hypothesis.

Nominal–Ordinal Generalized CMH

- Suppose that X (row) is nominal and Y (column) is ordinal.
- The responses on each row can be summarized by the mean score over the columns.
- The generalized CMH test statistic for conditional independence compares the I row means and is designed to detect whether the means are difference across the rows.
- If $H_O : \mu_{Y_j} = \mu_Y$ is true (i.e., the row means are all equal) or equivalently conditional independence between X and Y given Z , then the statistic is approximately chi-squared distributed with $df = (I - 1)$.
- When the scores for $Y \sim \mathcal{N}(\mu_{Y_j}, \sigma^2)$, a 1–way ANOVA would be an appropriate test; that is, the nominal–ordinal generalized CMH statistic is analogous to a 1–way ANOVA.
- Using midranks are used as scores in the generalized CMH statistic is equivalent to the Kruskal–Wallis (non-parametric) test for comparing mean ranks.

Example of Nominal–Ordinal Generalized CMH

On the handout, the second Cochran–Mantel–Haenszel statistic labeled

“Row Mean Scores Differ”

corresponds to the test for conditional independence between nominal SES and ordinal program type.

In our example, it make more sense to let program type be nominal, which yields

Statistic	Alternative Hypothesis	<i>df</i>	Value	<i>p</i>
1	Nonzero correlation	1	46.546	< .001
2	Row Mean Scores Differ	2	49.800	< .001
3	General Association	4	51.639	< .001

● Nominal–Ordinal Case

Example: Nominal–Ordinal Generalized CMH

We can compute the mean SES scores for each program type for each gender, e.g.,

$$[1(15) + 2(44) + 3(12)] / (15 + 44 + 12) = 139/71 = 1.96$$

Gender	School Program	SES			Mean
		Low 1	Middle 2	High 3	
Females	VoTech	15	44	12	$139/71 = 1.96$
	General	19	30	11	$112/60 = 1.87$
	Academic	16	70	56	$324/142 = 2.28$
Males	VoTech	30	38	8	$130/76 = 1.71$
	General	31	40	14	$153/85 = 1.80$
	Academic	28	77	61	$365/166 = 2.20$

● Nominal–Ordinal Case

Nominal–Nominal Generalized CMH

- This CMH test statistic is a test of “general association”.
- It is designed to detect any pattern or type of association that is similar across tables.
- Both X and Y are treated as nominal variables.
- The CMH test of general association is the efficient score test of $H_0 : \text{all } \lambda_{ij}^{XY} = 0$ in the (XY, XZ, YZ) log-linear model.
- If the null is true, then the statistic is approximately chi-squared distributed with $df = (I - 1)(J - 1)$.

High School & Beyond example (all CMH tests):

Statistic	Alternative Hypothesis	df	Value	p
1	Nonzero correlation	1	46.546	< .001
2	Row Mean Scores Differ	2	49.800	< .001
3	General Association	4	51.639	< .001

n

Models for SES × Gender × Program type:

Model	<i>df</i>	G^2	<i>p</i>
(GS,GP,SP)	4	1.970	.741
(GS,GP)	8	55.519	< .0001
(GP,SP)	6	8.532	.202
(SG,SP)*	6	3.312	.769
(GP,S)	10	62.247	< .0001
(GS,P)	10	57.027	< .0001
(G,SP)*	8	10.040	.262
(G,SP)-L × L*	11	16.221	.133
(G,P,S)	12	63.754	< .0001

The simplest model that appears to fit the data:

$$\log(\mu_{ijk}) = \lambda + \lambda_i^S + \lambda_j^P + \lambda_k^G + \beta u_i v_j$$

Sparse Data

and Incomplete Tables Methodology

1. Types of empty cells (sampling and structural zeros).
2. Effects of sampling zeros and strategies for dealing with them.
3. Fitting models to tables with structural zeros.

A “**Sparse**” table is one where there are “many” cells with “small” counts.

How many is “many” and how small is “small” are relative. We need to consider both

- The sample size n (i.e., the total number of observations).
- The size of the table N (i.e., how many cells there are).

X^2 and G^2

Types of Empty Cells

- **Sampling Zeros** are ones where you just do not have an observation for the cell; that is, $n_{ij} = 0$. In principle if you increase your sample size n , you might get $n_{ij} > 0$.

$$P(\text{getting an observation in a cell}) > 0$$

- **Structural Zeros** are cells that are theoretically impossible to observe a value.

$$P(\text{getting an observation in a cell}) = 0$$

Tables with structural zeros are “**structurally incomplete**”.

This is different from a “**partial classification**” where an incomplete table results from not being able to completely cross-classify all individuals.

X^2 and G^2

- It is important to recognize that a table is incomplete.
- Determine why it is incomplete, because this has implications for how you deal with the incompleteness.
- If you have structural zeros or an incomplete classifications you should NOT
 1. Fill in cells with zeros
 2. Collapse the tables until the structurally empty cells “disappear”.
 3. Abandon the analysis.

Effects of Sparse Data

Sampling Zeros

1. Problems that can be encountered when modeling sparse tables.
2. The effect of sparseness on hypothesis testing.

Problems in modeling Sparse Tables.

There are two major ones:

1. Maximum likelihood estimates of loglinear/logit models may not exist.
2. If MLE estimates exist, they could be very biased.

X^2 and G^2

- Depending on what effects are included in a model and the pattern of the sampling zeros determines whether non-zero and finite estimates of odds ratios exist.
- When $n_{ij} > 0$ for all cells, MLE estimates of parameters are finite.
- When a table has a 0 marginal frequency and there is a term in the model corresponding to that margin, MLE estimates of the parameter are infinite.

Hypothetical example

(from Wickens, 1989):

	$Z = 1$				$Z = 2$				$Z = 3$			
$Y =$	1	2	3	4	1	2	3	4	1	2	3	4
$X = 1$	5	0	7	8	9	8	3	12	6	3	5	11
$X = 2$	10	0	6	7	8	3	0	9	0	2	8	11

The 1-way margins of this 3-way table:

X	
1	2
77	64

Y			
1	2	3	4
38	16	29	58

Z		
1	2	3
43	52	46

X^2 and G^2

The iterative algorithm that the computer used to compute MLE of a model do not converge.

In SAS/GENMOD, in the `log` file you find the following

WARNING:

The negative of the Hessian is not positive definite. The convergence is questionable.

The procedure is continuing but the validity of the model fit is questionable. The specified model did not converge

Note: This is using the Wicken's data.

Signs of a problem

The estimated standard errors of parameters and fitted counts are high relative to the rest. They “blow up”.

For example, when the (X, YZ) joint independence model is fit to the hypothetical table using SAS/GENMOD,

$$\hat{\lambda}_{21}^{YZ} = -23.9833, \quad \text{ASE} = 87,417.4434$$

while all other ASE’s are less than .70.

$$\hat{\mu}_{121} = 7.15 \times 10^{-11}, \quad \log(\hat{\mu}_{121}) = -23.3519, \quad \text{std err} = 87,417$$

$$\hat{\mu}_{221} = 5.94 \times 10^{-11}, \quad \log(\hat{\mu}_{121}) = -23.3468, \quad \text{std err} = 87,417$$

● Model Building and Log-linear Models

X^2 and G^2

- Sparseness can cause
 - ◆ The sampling distribution of fit statistics will be poorly approximated by the chi-squared distribution.
 - ◆ Odds ratio estimates to be **severely biased**
- **Solution:** add .5 to each cell in the table.
- Adding .5 shrinks the estimated odds ratios that are ∞ to finite values and increases estimates that are 0.
- **Qualifications:** For unsaturated models, adding .5 will over smooth the data.
- **Remedies/Strategies/Comments:**
 - ◆ An infinite estimate of a model parameter maybe OK, but an infinite estimate of a true odds ratio is “unsatisfactory”.
 - ◆ When a model does not converge, try adding a tiny number (e.g., 1^{-8}) to all cells in the table.
 - ◆ Do a sensitivity analysis by adding different numbers of varying sizes to the cells (e.g., 1^{-8} , 1^{-5} , .01, .1). Examine fit statistics and parameter estimates to see if they change very much.

Example: Hypothetical Data

and the (X, YZ) loglinear model:

Number added	G^2	X^2	Converge?	ASE for $\hat{\lambda}_{21}^{YZ}$
—	16.86	13.38	no	87,417.44
0.00000001	15.43	17.92	yes	7,071.07
0.000001	16.83	13.37	yes	223.61
0.0001	16.87	13.38	yes	22.37
0.1	18.86	13.78	yes	2.30

Alternative: Use an alternative estimation procedure (i.e., Bayesian).

Effect of Sparseness on X^2 and G^2

Guidelines:

- When $df > 1$, it is “permissible” to have the $\hat{\mu}$ as small as 1 so long as less than 20% of the cells have $\hat{\mu} < 5$.

Empathy data: 37.5% of cells equal 0.

- The permissible size of $\hat{\mu}$ decreases as the size of the table N increases.
 - The chi-squared distribution of X^2 and G^2 can be poor for sparse tables with both very small and very large $\hat{\mu}$'s (relative to n/N).
- Empathy data:** sample size/size of table
= $178/16 = 11\dots$ maybe OK.
- No single rule covers all situations.
 - X^2 tends to be valid with smaller n and sparser tables than G^2 .

● Log-Linear Models &

Empathy Data

● Effect of Sparseness on

X^2 and G^2

Effect of Sparseness on X^2 and G^2

Guidelines (continued):

- G^2 usually is poorly approximated by the chi-squared distribution when $n/N < 5$.

The p -values for G^2 may be too large *or* too small (it depends on n/N).

- For fixed n and N , chi-squared approximations are better for smaller df than for larger df .

G^2 for model fit may not be well approximated by the chi-squared distribution, but the distribution of difference between G^2 's for two nested models maybe.

Chi-squared comparison tests depend more on the size of marginal counts than on cell sizes in the joint table.

So if margins have cells > 5 , the chi-squared approximation of $G^2(M_0) - G^2(M_1)$ should be reasonable.

X^2 and G^2

Cressie-Read statistic

Cressie, N, & Read, T.R.C. (1984). Multinomial goodness-of-fit tests. *Journal of the Royal Statistical Society*, 43, 440–464. They proposed a family of statistics of the form

$$RC^2 = \frac{2}{\lambda(\lambda + 1)} \sum_{i=1}^N n_i \left[\left(\frac{n_i}{\hat{\mu}_i} \right)^\lambda - 1 \right]$$

where $-\infty < \lambda < \infty$.

The value of λ defines a specific statistic (note: λ here is not a parameter of the loglinear model).

For

$$\lambda = 1, RC^2 = X^2.$$

$$\lambda \rightarrow 0, RC^2 = G^2.$$

$\lambda = 2/3$ works pretty well for sparse data. The sampling distribution of RC^2 is approximately chi-square.

Modeling Incomplete Tables

While structural zeros (and partial cross-classifications) are not as common as sampling zeros, there are a number of uses of the methodology for structurally incomplete tables:

1. Dealing with anomolous cells.
2. Excluding “problem” sampling zeros from an analysis.
3. Check collapsibility across *categories* of a variable.
4. Quasi–independence.
5. Symmetry and quasi–symmetry.
6. Marginal homogeneity.
7. Bradley–Terry–Luce model for paired comparisons.
8. (Guttman) scaling of response patterns.
9. Estimate missing cells.
10. Estimation of population size.
11. Other.

We’ve discuss 1, 2, and 3 now, and later 4, 5 and 6. (For the others, check Fienberg text and/or Wickens texts.)

● Capturing the Association
Model Building for Logit and Log-linear Models

● Comparing Adjusted
Residuals

The Methodology

- We remove the cell(s) from the model building and analysis by only fitting models to cells with non-structural zeros.
- We can arbitrarily fill in any number for a structural zero, generally we just put in 0.
- To “remove” the (i, j) cell from the modeling, an indicator variable is created for it,

$$\begin{aligned} I(i, j) &= 1 && \text{if cell is the structural zero} \\ &= 0 && \text{for all other cells} \end{aligned}$$

When this indicator is included in a loglinear model as a (numerical) explanatory variable, a single parameter is estimated for the structural zero, which used up 1 df , and the cell is fit perfectly.

- Since structural zeros are fit perfectly, they have 0 weight in the fit statistics X^2 and G^2 .

● Farmer, Rotella, Anderson & Wardrop

● Capturing the Association Model Building for Logit and Log-linear Models

● Comparing Adjusted Residuals

Example: Teens and Health Concerns

$$I(2, 1) = 1 \quad \text{for the (2,1) cell}$$

$$= 0 \quad \text{otherwise}$$

A single equation for the saturated log-linear model is

$$\log(\mu_{ij}) = \lambda + \lambda_i^H + \lambda_j^G + \lambda_{ij}^{HG} + \delta_{21}I(2, 1)$$

The δ_{21} is a parameter that will equal whatever it needs to equal such that the (2,1) cell is fit perfectly (i.e., the fitted value will be exactly equal to whatever arbitrary constant you filled in for it).

For the independence model, we just delete the λ_{ij}^{HG} term from the model, but we still include the indicator variable for the (2, 1) cell.

What happens to degrees of freedom?

$$df = (\# \text{ of cells}) - (\# \text{ non-redundant parameters})$$

$$= (\text{usual } df \text{ for the model}) - (\# \text{ cells fit perfectly})$$

$$\begin{aligned}
 df &= (I - 1)(J - 1) - 1 \\
 &= (4 - 1)(2 - 1) - 1 \\
 &= 3 - 1 \\
 &= 2
 \end{aligned}$$

$G^2 = 12.60$, and $X^2 = 12.39$, which provide evidence that health concerns and gender are not independent.

When n_{21} is set equal to 0, the estimated parameters for the independence model are

$$\begin{aligned}
 \hat{\lambda} &= 4.5466 & \hat{\lambda}_1^G &= -1.1076 \\
 \hat{\lambda}_1^H &= -2.0963 & \hat{\lambda}_1^G &= 0.0000 \\
 \hat{\lambda}_2^H &= -2.0671 & \hat{\delta}_{21} &= -22.9986 \\
 \hat{\lambda}_3^H &= -0.8307 & & \\
 \hat{\lambda}_4^H &= 0.0000 & &
 \end{aligned}$$

For the (2, 1) cell,

$$\hat{\mu}_{21} = \exp(4.5466 - 2.0671 - .1076 - 22.9986) \sim 0$$

Model Building for Logit and Log-linear Models

● Comparing Adjusted

Residuals

- A model fits a table well, except for one or a few cells.
- The methodology for incomplete tables can be used to show that except for these cells, the model fits.
... Of course, you would then need to talk about the anomalous cells (e.g., speculate why they're not being fit well).
- Example (from Fienberg, original source Duncan, 1975): Mothers of children under the age of 19 were asked whether boys, girls, or both should be required to shovel snow off sidewalks. The responses were cross-classified according to the year in which the question was asked (1953, 1971) and the religion of the mother.

Example Anomalous Cells

Since none of the mothers said just girls, there are only 2 responses (boys, both girls and boys).

Religion	1953		1971	
	Boys	Both	Boys	Both
Protestant	104	42	165	142
Catholic	65	44	100	130
Jewish	4	3	5	6
Other	13	6	32	23

Gender (**G**) is the response/outcome variable and Year (**Y**) and Religion (**R**) are explanatory:

Model	df	G^2	p	X^2	p
(RY,G)	7	31.67	< .001	31.06	< .001
(RY,GY)	6	11.25	.08	11.25	.08
(RY,GR)	4	21.49	< .001	21.12	< .001
(RY,GY,GR)	3	0.36	.95	.36	.95

- Capturing the Association
- Model Building for Logit and Log-linear Models
- Comparing Adjusted

Residuals

A closer look at models

- The homogeneous association model fits well.
- The (RY,GY) model fits much better than independence, but fits significantly worse than (RY,GY,GR):

$$G^2[(RY, GY)|(RY, GY, GR)] = 11.25 - .36 = 10.89$$

with $df = 3$ and $p = .01$.

However, let's take a closer look at (RY,GY).

- The Pearson residuals from the (RY,GY) log-linear model

Religion	1953		1971	
	Boys	Both	Boys	Both
Protestant	.75	-1.05	.91	-.91
Catholic	-.84	1.18	-1.42	1.42
Jewish	-.29	.41	-.22	.22
Other	.12	-.17	.85	-.85

The 3 largest residuals → mothers who are Catholic. The model under predicts “both” and over predicts “boys”.

Deal Anomalous Cells

- **Question:** If we do not include Catholic mothers, would the model (RY,GY) or the logit model with just a main effect of year fit the data?
- Try the model that removes the 3 largest residuals (the 2nd row of the table)

$$\log(\mu_{ijk}) = \lambda + \lambda_i^R + \lambda_j^Y + \lambda_k^G + \lambda_{ij}^{RY} + \lambda_{jk}^{GY} + \delta_{212}I(2, 1, 2) + \delta_{221}I(2, 2, 1) + \delta_{222}I(2, 2, 2)$$

where the indicator variables are defined as

$$I(2, j, k) = \begin{cases} 1 & \text{if Catholic and } j \neq 1 \text{ and } k \neq 1 \\ 0 & \text{otherwise} \end{cases}$$

- We only need 3 indicators to “remove” the row for Catholic mothers. **Why?**
- This model has $df = 4$, $G^2 = 1.35$, and $X^2 = 1.39$. So the (RY,GY) model fits well without the second row of the table.

Residuals

Farmer, Rotella, Anderson & Wardrop

The logit model without Realistic and Social:

$$\text{logit}(\pi_w) = \alpha + \delta^R I_R(i) + \delta^S I_S(i)$$

where

$$I_R(i) = \begin{cases} 1 & \text{if code is Realistic} \\ 0 & \text{otherwise} \end{cases}$$

$$I_S(i) = \begin{cases} 1 & \text{if code is Social} \\ 0 & \text{otherwise} \end{cases}$$

This model has $df = 3$, $G^2 = 4.32$, $p = .23$, and fits pretty good.

Recall that the residuals from the independence models for realistic and social are both quite large but opposite signs.

- Model Building for Logit and Log-linear Models
- Comparing Adjusted Residuals

Capturing the Association

Let's define a new variable to capture the suspected association structure,

$$I(i) = \begin{cases} -1 & \text{if code is Realistic} \\ 1 & \text{if code is Social} \\ 0 & \text{otherwise} \end{cases}$$

and fit the model

$$\text{logit}(\pi_w) = \alpha + \beta I(i)$$

This model has $df = 4$, $G^2 = 4.54$, $p = .24$. This fits almost as good as the model in which the odds for realistic and social are fit perfectly:

$$\Delta G^2 = 4.54 - 4.32 = .22$$

with $\Delta df = 4 - 3 = 1$, which is the likelihood ratio test of $H_0 : \beta^{\text{social}} = -\beta^{\text{realistic}} = \beta$.

Interpretation

$\hat{\beta} = 2.9240$ with $ASE = .7290$.

- Gender and codes are independent, except for the codes other than Realistic and Social.

- The odds that a woman (versus a man) with a science career has a primary code of Social is

$$\exp \left[\hat{\beta}(1 - (-1)) \right] = \exp(2(2.9240)) = e^{5.848} = 346.54$$

times the odds that the career has a primary code of Realistic.

- The odds ratio of Social versus Other than Realistic equals

$$\exp \left[\hat{\beta}(1 - 0) \right] = \exp(2.9240) = 18.62$$

- The odds ratio of Realistic versus Other than Social equals

$$\exp \left[\hat{\beta}(0 - 1) \right] = \exp(-2.9240) = 1/18.62 = .05$$

Collapsing Over Categories

Returning to the snow shovelling data, rather than deleting Catholics, perhaps the effect of religion on the response can be accounted for by a single religious category. If so, then we can collapse the religion variable and get a more parsimonious and compact summary of the data.

To investigate this, we replace religion by a series of 4 binary variables

P = Protestant (i.e., $P = 1$ if Protestant, 0 otherwise).

C = Catholic (i.e., $C = 1$ if Catholic, 0 otherwise).

J = Jewish (i.e., $J = 1$ if Jewish, 0 otherwise).

O = Other (i.e., $O = 1$ if not **P**, **C**, or **J**, and 0 otherwise).

Using all 4 variables (instead of just 3), we introduce redundancy in the data. This allows us to treat the 4 categories of religion symmetrically.

Models for Snow Shovelling

Since G (gender) is considered the response and all log-linear models must include λ^{YPCJO} terms (and lower order ones). Here are some of the fit to the data models.

Model	df	G^2
Fit previously		
(YPCJO,GY)	6	11.2
(YPCJO,GY,GPCJO)	3	0.4
New ones		
(YPCJO,GY,GO)	5	9.8
(YPCJO,GY,GJ)	5	10.9
(YPCJO,GY,GC)	5	1.4
(YPCJO,GY,GP)	5	4.8

The (YPCJO,GY,GC) model which has a main effect for year (GY) and an effect of being Catholic fits well.

In other words, the interaction between religion and response is due primarily to Catholic mothers.

In this example, we can collapse religion into a single dichotomous variable (Catholic, Not Catholic).

SAS/GENMOD to fit the $L \times L$ association model
